ABSTRACT

We consider the problem of interpolating a signal in $I\!R^d$ known at a given resolution. In our approach, the signal is assumed to belong to a given (large) class of signals. This class is characterized by local regularity constraints, that can be described by a certain inter-scale behaviour of their wavelet coefficients. These constraints allow to predict the scale n coefficients from the ones at lower scales. We investigate some properties of this interpolation scheme. In particular, we give the Hölder regularity of the refined signal, and present some asymptotic properties of the method. Finally, numerical experiments are presented. Both the theoretical and numerical results show that our regularity-based scheme allows to obtain good quality interpolated images.

1. INTRODUCTION AND BACKGROUND

A ubiquitous problem in signal and image processing is to obtain data sampled with the best possible resolution. At the acquisition step, the resolution is limited by various factors such as the physical properties of the captors or the cost. It is therefore desirable to seek methods which would allow to increase the resolution after acquisition. This is useful for instance in medical imaging or target recognition. At first sight, this might appear hopeless, since one cannot "invent" information which has not been recorded. However, there are a number of situations of practical interest where this can be done. A first class of such situations is when several low resolution overlapping signals are available. This occurs in video sequences, radar imaging or MRI. Interpolation (also called superresolution in this context) is then the process of combining these multiple low resolution signals into a high resolution one. This is not the frame we shall consider here.

In more general situations, a single signal is available for interpolation. Compared with the case above, one needs to supplement the data brought by the low resolution signal by a richer *a priori* information. Several methods have been explored, which may be roughly split into two types: In the first, "class-based" one, the signal is assumed to belong to some class, with conditions expressed mainly in the time or frequency domain. Such classes include band-limited or time-limited signals, positive and/or sparse signals, and smoothness classes such as C^n or Besov spaces $B_{p,q}^s$. This puts

constraints on the interpolation, which is usually obtained as the minimum of a two-terms cost-function: The first term ensures that the reconstructed high resolution image is compatible with the observed low resolution one. The second term corresponds to the *a priori* smoothness information. Works following this approach include [1, 2, 3, 4, 5, 6, 7].

The second type of approach, which could be called "contextual", has been proposed in recent papers originating from several communities (computer vision, computer graphics, AI) [8, 9, 10]. It originates from the observation that most class-based methods results in overly smooth images at higher interpolation rates (i.e. larger than 4). Contextual methods try to overcome this problem by using a "local learning" technique: Basically, the system is given some information about the local features in a given class of signals (a database). It then uses this information to compute a high resolution signal by comparing the local features of the signal to be processed with the ones of the signals in the database. The assumption is that neighbourhoods in the images of the database that are similar at resolutions $n, n-1, \ldots, n-i$, should remain so at the "superresolution" $n+1$. The methods then proceed by finding, for any neighbourhood in the image to be processed, similar neighbourhoods in the database, and then interpolating on the basis on the known high resolution versions of the database neighbourhoods.

A number of problems remain with most techniques developed so far: While the interpolated image is usually too smooth, it also occur sometimes that on the contrary too many details are added, in particular in smooth regions. In addition, the creation of details is not well controlled, so that one can neither predict how the high resolution image will look like, nor the theoretical properties of the interpolation scheme.

Let us now explain in informal terms how our method works. Broadly speaking, our main motivation is to find a way to interpolate in such a way that smooth regions as well as irregular ones (i.e. sharp edges or textures) remain so after zooming. We interpret this as a constraint on the the local regularity: The interpolation method should preserve the local regularity. The next step is to define an index of local regularity which is both a reasonable measure of the perceived regularity and mathematically/computationally tractable. In that view, we use a notion of Hölder exponent. Hölder exponents have been shown to correspond to an intuitive notion

of regularity in both images and 1D signals [11]. In order to control the interpolation and to obtain a simple implementation, we need to make some assumptions on the signal, to the effect that (a) this Hölder exponent can be easily estimated from wavelet coefficients (b) the Hölder exponent allows to predict the finer scales coefficients. Technically, this requires that the signal is not *oscillatory* (see section 2). This scheme allows to control both the reconstruction error and the regularity of the interpolated signal (this regularity does not depend on assumptions on the original signal). This regularity in turn controls the visual appearance of the added information, i.e. the (local) high frequency content.

To get an intuitive understanding of the method, it is useful to recast this in terms of wavelet coefficients: Let X denoted the input signal and let $d_{j,k}$ be its wavelet coefficients, where, as usual, j corresponds to scale and k to location. Roughly speaking, if a signal has regularity α at point t, then its wavelet coefficient $d_{j,k(j,t)}$ "above" t are bounded by $C2^{-j\alpha}$ for some constant C: $\forall j = 1 \ldots n, |d_{j,k(j,t)}| \leq C2^{-j\alpha}$. As said above, α correspond to an intuitive notion of regularity: A large α translates in a smooth signal, while $\alpha \in (0,1)$ means that the signal is continuous and non differentiable at t. If the signal is discontinuous at t but bounded, then $\alpha = 0$. Now if we are willing to preserve the regularity, we should prescribe the wavelet coefficient above t at the superresolved scale $n+1$ in such a way that $|d_{n+1,k(n+1,t)}| \leq C2^{-(n+1)\alpha}$.

For concreteness, let us explain schematically how our method would act in two simple situations: On a uniform region, all the wavelet coefficients are close to zero. The bound on the wavelet coefficients then holds with arbitrarily large α, since $0 \leq C2^{-j\alpha}$ for all $\alpha > 0$. As a consequence, the predicted coefficient $d_{n+1,k}$ will be zero, since it must satisfy the same inequality: The smooth region will remain smooth, because no detail will be added. On the other hand, above a step edge, the wavelet coefficients $d_{j,k}$ do not decay in scale. This imply that $\alpha = 0$. The predicted coefficient $d_{n+1,k}$ will then be of the same order as $d_{n,k}$. As a consequence, the local regularity of the interpolated image will be again equal to 0 at this point, and the edge will not be blurred.

We describe the interpolation procedure in the next section. Section 3 highlights some theoretical features of the method related to asymptotic regularity properties of the interpolated signal and bounds on the reconstruction error. Finally, section 4 displays some numerical experiments.

2. THE METHOD

Let X denote the original signal, and $X_n = (x_1^n, \ldots x_{2^n}^n)$ its regular sampling over the 2^n points $(t_1^n, \ldots t_{2^n}^n)$. Let ψ denote a wavelet such that the set $\{\psi_{j,k}\}_{j,k}$ forms an orthonormal basis of L^2. Let $d_{j,k}$ be the wavelet coefficients of X.

For $k = 1 \ldots 2^n$, we consider the point $t = t_k^n$ and the wavelet coefficients $d_{j,k(j,t)}$ which are located "above" it (ie $k(j,t) = \lfloor (t+1)2^{j+1-n} \rfloor$). Let $\alpha_n(t)$ denote the slope of

the liminf regression of the vector $(\log(d_{1,k(1,t)}, \ldots d_{n,k(n,t)})$ versus $(-1, \ldots, -n)$.

See [12] for an account on liminf regressions. When n tends to infinity, $\alpha_n(t)$ tends to liminf $\frac{\log d_{n,k(n,t)}}{-n}$. This number has been considered in the literature [13] under the name of *weak scaling* exponent, denoted β_w. It is a measure of the local regularity in the following sense. The weak scaling exponent of the signal X at t_0 is defined as:

$$\beta_w = \sup\{s : \exists n, \ X^{(-n)} \in C_{t_0}^{s+n}\}.$$

where $X^{(-l)}$ denotes a primitive of order l of X and $C_{t_0}^s$ is the usual pointwise Hölder space at t_0. When the local Hölder exponent α_l and the pointwise Hölder exponent α_p of X at t coincide, then β_w is also equal to their common value. See [14] for more on this topic. In the following we will always assume that this is the case. In other words, we consider that our signals belong to the class $\mathcal{S}$ defined as follows:

$$\mathcal{S} = \{X \in L^2(\mathbb{R}), \forall t \in \mathbb{R}, \alpha_p(t) = \alpha_l(t)\}$$

The class $\mathcal{S}$ may appear somewhat abstract to the reader. Here are a few clues. $\mathcal{S}$ contains all C^∞ signals and all signals of the type $\sum_{n \in \mathbb{N}} |t - t_n|^{\gamma_n}$, with $t_n \in \mathbb{R}, \gamma_n \in \mathbb{R}^+$. Many everywhere irregular signals are also in $\mathcal{S}$, such as the continuous nowhere differentiable Weierstrass function $\sum_{n \in \mathbb{N}} 2^{-nh} \sin(2^n t)$, $h \in (0,1)$. On the other hand, "chirp" signals as $|t|^\gamma \sin(1/|t|^\beta)$, $\gamma > 0, \beta > 0$ do not belong to $\mathcal{S}$. The easiest way to picture elements in $\mathcal{S}$ is maybe through their wavelet transform: At each point t, the "largest" coefficients are located above t in the following sense. Take any sequence $d_{j,k}$ of coefficients such that $k2^{-j}$ tends to t. Then, if X belongs to $\mathcal{S}$,

$$\liminf_{j \to \infty} \frac{\log |d_{j,k}|}{-j} \geq \liminf_{j \to \infty} \frac{\log |d_{j,k(j,t)}|}{-j} \qquad (1)$$

For a general continuous signal (i.e. a signal not in $\mathcal{S}$), the Hölder regularity at t may always be evaluated from the decay of *all* the wavelet coefficients $d_{j,k}$ such that $k2^{-j}$ tends to t (i.e. from liminf such as above). When the signal is in $\mathcal{S}$, inequality (1) implies that we may restrict our attention to the ones *above* t. Such signals are called "non-oscillatory" in the literature.

To perform the interpolation, we compute above each point t the regression of the wavelet coefficients *vs* scale. The parameters of the regression allow to build the extrapolated coefficient. These coefficients in turn determine the "superresolved" signal.

3. REGULARITY AND ASYMPTOTIC PROPERTIES

We give two properties of the regularity-based interpolation. See [15] for more results and proofs. Let $\tilde{X}_{n+m}$ the signal after m interpolations, $\tilde{\beta}_{n,k}$ the slope of the regression and $\log_2\left(\widetilde{K}_{n+1,k}\right)$ the ordinate in zero.

Proposition 1 *If $X \in C^\alpha$ then, whatever the number m of added scales:*

$$\parallel X - \tilde{X}_{n+m} \parallel_2^2 \leq \frac{c^2}{2}\frac{1}{2^{2\alpha}-1}2^{-2\alpha n} + \frac{\hat{K}_n}{2^{2\hat{\beta}_n}-1}2^{-2\hat{\beta}_n n}$$

With $(\widehat{K}_{n+1}, \widehat{\beta}_n)$ such as:

$$\widehat{K}_{n+1}2^{-2j(\hat{\beta}_n+\frac{1}{2})} = \max_{(\widetilde{K}_{n+1,k},\tilde{\beta}_{n,k})}\left[\widetilde{K}_{n+1,k}2^{-2j(\tilde{\beta}_{n,k}+\frac{1}{2})}\right]$$

Proposition 2 *Let X belong to S, and assume $X \in C^\alpha$. Then, $\forall \varepsilon > 0, \exists N$:*

$$n > N \Rightarrow ||X - \tilde{X}_{n+m}||_2 = \mathcal{O}(2^{-(n+m)(\alpha-\varepsilon)})$$

In addition,
$||X - \tilde{X}_{n+m}||_{B_{p,q}^s} = \mathcal{O}(2^{-(n+m)(\alpha-s-\varepsilon)})$ for all $s < \alpha - \varepsilon$.

4. NUMERICAL EXPERIMENTS

We present results of the regularity-based interpolation on two images. The first one is the well-known Lena image, the second is a scene containing a Japonese door (*toryi*). Both original images are 128x128 pixels and are shown on figure 1. Figure 2 displays a comparison between four-times bicubic and regularity-based interpolations on a detail of Lena. Figure 3 presents eight-times bicubic and regularity-based interpolations on a detail of the door image.
